

Alfalfa Fertility Experiment

An experiment was established during the late spring of 1967 to evaluate, primarily, the effect of method of application and rate of application of phosphate fertilizer on the yield and chemical analysis of alfalfa hay. Also, variables of potassium and zinc were included. Two locations were established; at the Madras Station the experiment was based on a period of five years and at the Bayless Farm in Powell Butte, a three-year period. The levels of phosphate fertilizer applied were equal in amount to annual applications of 60 and 120# of P_2O_5 for the respective locations with several of the plow-down and disc-in treatments being applied in one application prior to seeding and others as split applications with part incorporated prior to seeding and part as surface application during the following years of the experiment. Several fertilizer treatments were duplications of selected phosphate treatments with the exception that 60# of P_2O_5 was banded at seeding time to the side of the seed as mono-ammonium phosphate (11-48).

The 1968 harvest is the first year of harvest for the experiment and the results are shown by cutting in Table Nos. 11 and 13 with a summary of yield and plant analysis in Table Nos. 12 and 14. There was no significant difference in yield by cutting or the season's total yield at the Madras location. The variation between replications at the Bayless location was even greater. Consequently, no analysis was calculated. However, the yields at either location would be considered acceptable by the farmer.

The soil test at the Madras location indicated a phosphate level approximately twice as high as the Bayless location and the plant analysis reflected some of the difference although the plant phosphate level at both locations would be considered adequate. By some published standards both the calcium and magnesium levels of the plants would be considered deficient. However, the soil test levels were generally adequate to high in these elements.

The level of zinc in the plants would be considered borderline to low but the application of 30# $ZnSO_4$ had no apparent effect on the presence of zinc in the plant sample.
